

Proof of Controls

Verifiable risk controls for scaling DeFi insurance.

Prepared for Aon · 2026

Vault coverage scales when carriers can trust the controls.

Verified controls let rates fall. Falling rates let coverage scale: more vaults covered, larger limits, more carriers writing. Premium dollars grow with all of it.

~5%

Today

~3.5–4%

Strong controls, self-enforced

2%

Target rate with independent verification

High premiums must price in two kinds of uncertainty.

No shared standard

Every vault defines controls its own way, so every review starts from scratch.

No independent verification

Underwriting review at binding, investigation at claim. Between the two, compliance is self-asserted.

Lapsed Control Scenario

Twenty controls verified at binding. One lapses for a week; a loss occurs during the lapse; the control is restored; the claim is filed. No one can prove the state of the controls at the time of loss, so carriers price that scenario into every policy.

The consortium writes the standard. Newton makes it verifiable.

Risk controls, enforced before settlement. Provable at any moment.

Controls expressed as rules

Written in Rego, referencing the data that decides them: audit registries, oracle configurations, price feed sources, sanctions lists, signing state. Onchain or offchain.

An independent network enforces them

Rules are evaluated by Newton's operator network rather than the curator or platform. Evaluation completes before the transaction settles; transactions proceed only if the checks pass.

Every evaluation is attested onchain

Each evaluation produces an onchain attestation, and every rule version is a permanent onchain artifact. What was enforced, what was checked, and what changed is public record.

Control requirements become verified conditions.

Today	With Newton
Controls verified once, at binding	Controls verifiably enforced at every vault operation
Compliance self-asserted for the term	Compliance attested onchain, continuously
Breach discovered in claims investigation	Breach blocked before settlement, or visible the moment it occurs
State at time of loss reconstructed after the fact	State at time of loss is an onchain lookup
Control changes surface at the next review (if ever)	Control changes are themselves onchain events
No independent enforcement record	Every month of verified controls accumulates into enforcement and loss history

At claim time, no one has to reconstruct what was true; the record is there. And the record compounds into the dataset actuaries can eventually rate against: pricing by demonstrated enforcement rather than by category.

The consortium writes the rules. Newton proves the rules were in place.

Written standard

The consortium publishes its control framework: the criteria a coverable vault must meet.

Enforceable pack

Each control is written as an enforceable rule. The rules compose into a versioned onchain pack. Updates propagate to adopting vaults; version history is public.

Verified adoption

A carrier quoting a vault checks one thing: the pack is in force and enforced. Attestations show it continuously, for the life of the policy.

One pack, adopted across vaults, verifiable by any carrier.

Carrier requirements: from checklist to code.

**Verified**

Audits current

Checks audit status against the registry at each operation.

**Verified**

Contract unchanged

Flags material change to vault code or configuration the moment it occurs.

**Enforced**

Oracle standards

Requires approved providers, configurations, and minimum feed source counts.

**Enforced**

Allocation scope

Re-checks any new market against the underwritten scope before funds move.

**Enforced**

Signing quorum

Confirms the required MPC quorum approved each transaction.

**Enforced**

Sanctions screening

Screens counterparties against sanctions data at evaluation.

Enforced: a failed check blocks settlement. Verified: state attested onchain, visible immediately.

Any control referencing observable data can be written as a rule. When the consortium publishes its framework, the framework becomes the pack.

Rules reference data through the curator's own provider subscriptions. Newton adds no markup and holds no data.

A live window on every covered vault.

The transparency dashboard.

Controls in force and every enforcement decision as vault operations settle. Per vault, shared with the carrier on the risk for the life of the policy. Compliance is visible; positions and strategy are not.

The same view depositors see.

Nothing prepared for the carrier, nothing withheld from the market. The record that satisfies the carrier also markets the vault to allocators.

Provisioned through Aon.

Access for Aon teams, clients, and the carrier on each risk. Everything on it is backed by public onchain attestations. Nothing to integrate.

Evaluation record — every decision attested onchain.

Four roles, one product.

The consortium

Defines the control framework: what a coverable vault meets.

Newton

Turns the framework into enforceable rules, enforces them before settlement, attests every evaluation onchain.

Aon

Brings the framework to clients and carriers as an Aon-branded offering, powered (and verified) by Newton.

STG

Operationalizes: documentation, carrier strategy, the path from framework to bound policies.

A natural extension: Aon or a trusted consortium member operates a node in the verification network itself.

A verification layer for every digital asset line.

DeFi vaults

The consortium product: this deck. Wallet controls included: signing quorum and key configuration verified per transaction.

Treasury & wallet management

Spend limits, counterparty restrictions, and approval workflows for institutional wallets.

Real world assets

Investor eligibility, jurisdictional and transfer restrictions, enforced at the token level.

Stablecoins & protocols

Issuance and redemption controls.

The controls recur across lines: screening, quorum, scope. One rule library, recombined by line, verified the same way.

SOC 2 Type II

ISO 27001

We solved onboarding for 56M accounts. Now we solve authorization.

Newton Labs, formerly Magic Labs. Our wallet infrastructure served 56M+ accounts across consumer and institutional applications, including Polymarket, before Payward, Kraken's parent company, acquired the wallet business.

Newton is the authorization layer for onchain finance.

TIGERGLOBAL

SOCIALCAPITAL

synchrony

polygon

Commercials: aligned by design.

Principle: Aon nets more on a Newton-verified placement than on any placement without one.

Program

Aon holds the program: \$200K annually, creditable in full against share revenue. Covers the consortium pack, provisioning for Aon teams, clients, and carriers, and enablement through STG.

Share

Newton earns a share of placement economics that steps with verification intensity (ie, curator activity): 17.5% passive, 20% active, 22.5% high-frequency strategies. Set at binding, re-rated at renewal. Aon keeps the rest.

Upside

Carriers pay profit commissions when a book outperforms its pricing. If the verified book runs cleaner, Newton participates in that outperformance alongside Aon. Upside that exists only if verification works.

THE CURATOR’S VIEW

	Standards, self-enforced	Verified
Rate	~3.5–4%	2%
Annual premium, \$25M limit	~\$875K–1M	\$500K
Verification cost to curator	—	\$0

Curators never see a verification line. Verified placement is simply the better rate, through Aon.

A service, not monitoring: the same dashboard markets the vault to allocators, and curators extend the pack with their own rules within the framework.

Data stays direct: the curator’s existing provider subscriptions power the rules. Newton adds no markup and holds no data.

A starting structure to be shaped with STG.

From framework to first bound policy.

1. Now

Map the consortium's draft framework to an enforceable pack, in step with the September publication.

2. September

STG working session: product access, commercial structure, carrier materials.

3. New York event

The consortium event. Verification live in front of the carriers in the room.

4. The pilot

One live vault, quoted three ways: baseline, standards self-enforced, standards verified. The deltas are the proof.

Under the hood: the verification network.

Every evaluation is executed by a decentralized operator network, cryptographically signed, and verified onchain before the vault operation settles.

1. Intent submitted

When a transaction hits the vault contract, it is packaged as an intent and broadcast to Newton's operator network — the same network securing every evaluation across every Newton-integrated contract.

2. Operators evaluate and sign

Operators pull the offchain data the rules require — sanctions lists, identity checks, oracle health — run the rule logic, and sign the result. Once quorum is reached, signatures aggregate into a single BLS attestation.

3. Enforcement, onchain

The attestation is submitted to the contract, which verifies it and approves or rejects the transaction. No single operator can be compromised or coerced. Newton is privacy-preserving, using a combination of TEE, MPC, and ZK tech, to protect any sensitive data.

Three integration paths.

Preferred

Newton Shield, in front of the curator's wallet.

Deploy Shield and delegate curator control to it. Every instruction is evaluated before it reaches the vault, so nothing settles unless it passes. Wallet controls like signer quorum become independently verifiable, and rules the wallet cannot express are added in the same step. No change to the vault contract, no redeployment, no new audit — the best path for vaults that are already live.

In the vault contract.

A lightweight client in the vault itself. Works with Veda's Hook module, Morpho's Gate contracts, Lagoon's Whitelist Manager, and any ERC-4626 vault.

At deployment.

New vaults launch through Newton's vault launchpad with Shield integrated from the start. At launch, works with Veda, Morpho, and Aave, with more support to come.

The contract path: a single `require()` statement.

Evaluation completes in under two seconds on each path.
